Abstract: AgSnO₂ composites prepared by a reaction synthesis method were investigated. The phases of AgSnO₂ composites were analyzed using X-ray diffraction. The microstructure, density, hardness and resistivity of AgSnO₂ composites after four-pass accumulative roll bonding (ARB) at 973 K were analyzed. Results show that microstructure and properties of AgSnO₂ composites are significantly affected by the ARB process. The pass number of ARB decides the distribution of SnO₂ particles in silver matrix. Roll bonding can promote the uniform distribution of SnO₂ particles in silver matrix; however, it can also cause second agglomeration of SnO₂ particles due to stacking. With the increasing of ARB number, the density and hardness increase. The resistivity has a slight reduction at the first-pass roll bonding, but then it increases with the increasing of ARB number.

Key words: reaction synthesis method; AgSnO₂ composites; accumulative roll-bonding

As one of the main electrical contact materials, silver metal oxide (AgMeO) composites have been widely used because of their excellent electrical contact characteristics^[1,2]. For a long time, the application of electrical contact materials is mainly focused on AgCdO composites in China. However, Cd is a kind of toxic substances. Therefore, a large amount of Ag alloy material and other composites used to replace AgCdO composites were investigated. As a better replacement to AgCdO, AgSnO₂ composites show excellent arc erosion resistance, abrasion resistance, good anti-welding and some unique electrical contact characteristics^[3,4]. But some recent researches have found that some problems in application exist in AgSnO₂ electrical contact materials^[5,6]. In the electrical contact property test, AgSnO₂ composites showed rising contact resistance with the increasing of current. Another problem is that AgSnO₂ composites have a high

hardness, which makes the forming difficult. Therefore, it may take a long time for AgSnO₂ composites to be used as a replacement of AgCdO.

Traditional researches focused on the composition design of electrical contact materials and achieved fruitful results, but very few researches considered the processing technology. Accumulative roll bonding (ARB) is effective means for the preparation of ultrafine grained materials^[7]. The current ARB technology was mainly used in steel and aluminum alloy^[8-10], but it is relatively rare in electrical contact materials. In the present paper, the microstructure of AgSnO₂ composites by ARB was studied and the density, hardness and electrical conductivity were tested.

1 Experiment

The silver powder with 45 μm particle size and purity > 99.95% and other reactants were used as starting materials

to fabricate AgSnO_2 composites by a reaction synthesis method. The content of SnO_2 was 10 wt% in AgSnO_2 composites. The raw powder was mixed in planetary ball mill, and the mixed raw powder was pressed as a cylindrical body at 310 MPa. Then the cylindrical body was sintered in a vacuum sintering furnace at 800 K for 2 h. To increase the density of AgSnO_2 composites, re-sintering and re-pressing were adopted. AgSnO_2 sample of $\Phi 2.0 \text{ mm} \times 209.5 \text{ mm}$ was obtained by extrusion at different temperatures.

ARB process of primary AgSnO_2 sample involved three main aspects. Firstly, 50% reduction per pass was obtained by hot rolling with a rate of 1200 mm/min. Before the next step, the annealing treatment at 573 K was needed in order to avoid the influence of residual stress. Secondly, the sample after rolling was cut and stacked to be the initial thickness, which was treated as the raw sample for next step. Thirdly, ARB process was repeated 4 times at 973 K. Before ARB process, the sample was preheated at 973 K for 5 min after annealing treatment at 573 K.

The hardness of the samples was measured by Vivtorinox hardness tester^[11]. The average value of sample density was calculated using size and quality of each sample, which were measured 5 times for ensuring the repeatability. The resistance of the AgSnO_2 sample was measured using digital DC resistance tester (measuring accuracy: 0.02%) at room temperature. Microstructure of AgSnO_2 sample was observed using an optical microscope. X-ray diffraction (XRD) was used to analyze the phase composition of the sample.

2 Results and Discussion

2.1 Phase analysis

The X-ray diffraction results for AgSnO_2 composites before ARB process is shown in Fig.1. From Fig.1, it is clear to see that the AgSnO_2 composites can be fabricated by the reaction synthesis method and the phase composition are silver and tin oxide.

2.2 Microstructure

The microstructure of samples after different ARB processes is shown in Fig.2. From Fig.2, the SnO_2 particles in AgSnO_2 composites present an agglomeration state (A region in Fig.2a), but then they show a dispersed state with the increasing of roll pass (Fig.2b). Finally SnO_2 particles exhibit an agglomeration state again (B region in Fig.2d).

Fig.1 XRD pattern of the sample before ARB process

From Fig.2a to Fig.2b, the agglomerate SnO_2 particles change into dispersed state through first pass ARB, namely SnO_2 particles are evenly distributed in the silver matrix. The reason is that initial agglomerate SnO_2 particles in the sample are probably dispersed by strongly stress of ARB process.

With the increasing of roll pass, the agglomerate SnO_2 particles appear again (Fig.2d). This can be explained that the sample was cut and stacked after the first pass, which lead to overlap together of SnO_2 particles in the next procedure.

2.3 Property analyses

2.3.1 Density and hardness

The density and hardness variation of samples after ARB process are shown in Fig.3. The density and hardness of AgSnO_2 composites show an upward tendency with the increasing of rolling passes. The results can be summarized as follows:

On the one hand the frictional force is generated between the roller and the composites, which leads to the strong shear deformation in the AgSnO_2 composites. The SnO_2 particles are dispersed in Ag matrix with shear deformation. This causes the dislocation stacking near SnO_2 particles and strengthens dispersion^[12].

On the other hand the surface of the AgSnO_2 composites is brought into the internal structure during the ARB process, which leads to plenty of compound interface in the AgSnO_2 composites. Some impurities in roller surface are also brought

Fig.2 Microstructures of AgSnO_2 during ARB at 973 K: (a) primary sample, (b) 1-pass, (c) 2-pass, and (d) 4-pass

Fig.3 Relationship between density, hardness of AgSnO₂ composites and rolling passes

into the inner of AgSnO₂ composites under the rolling force. So the hardness of the samples increases gradually under the influence of the composite interface and impurities.

Hardness and density of the AgSnO₂ sample are also affected by elimination of the pore structure, vacancies and other defects in the ARB process. Therein, the pores are one of the main defects in AgSnO₂ composites by reaction synthesis. The disappearance of pores greatly improves the density and hardness of AgSnO₂ composites in a certain extent due to the ARB process.

In addition, research shows that the changes of hardness is related to grain refinement as well as the changes of grain boundaries^[13,14]. In AgSnO₂ composites, the fine dislocation cell structure in the Ag matrix organization may be produced at the early pass of ARB process, which leads to dislocation pile at the next ARB process. With the increasing of strain, fine dislocation cells may be developed into ultrafine subgrains due to dislocation pile in Ag matrix. This will refine grains of Ag matrix, which produces fine grain strengthening and affects the hardness of AgSnO₂ composites.

From Fig.3, the hardness (HV) of AgSnO₂ composites changes from 884.364 MPa to 1150.992 MPa with variation rate of 30.1% after the first rolling pass. But from the third to the fourth pass, the hardness changes from 1534.796 MPa to 1592.758 MPa with variation rate of only 3.89%. It seems that the ARB process does not definitely increase the hardness of AgSnO₂ composites. It is attributed to the common role of elimination of the pore structure or vacancies and significant grain refinement at the first rolling pass. There is no elimination of the pore structure or vacancies at the third to the fourth pass due to density increase after the second rolling pass.

2.3.2 Resistivity

Rolling pass effect on resistivity of AgSnO₂ composites is shown in Fig.4. The resistivity of the AgSnO₂ composites increases after an initial decrease during the ARB process.

Fig.4 Relationship between resistivity of AgSnO₂ composites and rolling passes

The resistivity of sample declines from 2.498 μΩ·cm to 2.411 μΩ·cm after the first pass. This is attributed to a high density, microstructure homogenization, and few structure defects of AgSnO₂ composites through ARB. Then the resistivity of AgSnO₂ composites increases, which results from the residual stress and SnO₂ particles agglomeration again (Fig.2).

The rolling process can produce strong strain and poor wettability between the Ag and SnO₂. It is inevitable that SnO₂ particles are enriched in the AgSnO₂ samples during rolling process. This leads to the stress concentration in partial area of the AgSnO₂ composites. Quinn et al.^[15] suggested that the resistance of the metal originates from ion scattering of conduction electrons. Stress concentration causes the interface distortion of AgSnO₂ composites, which leads to electronic strong scattering and finally increases the resistivity of AgSnO₂ samples.

In the metal matrix composites, electronic transmission can be reduced because of the interface scattering. This scattering process has become the main factor affecting the resistivity of composites. For AgSnO₂ composites, SnO₂ particles are gradually dispersed during ARB process (Fig.2), which leads to plenty of interface increase between SnO₂ and the Ag matrix, and then increases the resistivity of AgSnO₂ composites.

In addition, the distribution of SnO₂ particles may impact the resistivity of AgSnO₂ composites. Before ARB process, SnO₂ particles are distributed in the silver matrix with three-dimensional network structure. However, due to stack, it shows a kind of layered structure after ARB process.

3 Conclusions

1) AgSnO₂ composites with a homogeneous structure are obtained by ARB. During the ARB process, the AgSnO₂ composites are rolled with a 50% reduction ratio per pass at 973 K. Then, the rolled sheet is cut and stacked to the initial thickness, and the stacked piece is rolled again. But after

4-passes rolling, SnO_2 particles agglomerate again in the structure of AgSnO_2 composites.

2) During ARB at the constant rolling temperature, the hardness and density of AgSnO_2 sample increase with the increasing of rolling pass. This is attributed to the elimination of the pore structure, vacancies and other defects, as well as dispersion strengthening and fine grain strengthening.

3) The resistivity change is dominated by the contribution of SnO_2 particles in the AgSnO_2 composites and interface scattering.
