Abstract: Electrode materials of $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ were synthesized by hydrolysis precipitation process. After calcination at various temperatures, the materials were characterized by X-ray diffraction (XRD), transmission electron microscopy (TEM) and thermogravimetric analysis (TGA). XRD patterns confirm that the structure of $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ is tetragonal (rutile). TEM images reveal the morphology of the $\text{SnO}_2 \cdot x\text{H}_2\text{O}$. TGA shows the water content in $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ decreases as the calcination temperature increases. Electrochemical tests, such as cyclic voltammetry (CV), chronopotentiometry and cycling were also performed to study the supercapacitor behavior of $\text{SnO}_2 \cdot x\text{H}_2\text{O}$. CV results indicate that $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ calcined at 200 °C has a specific capacitance of 36.1 F/g at the scan rate of 5 mV/s in 0.5 mol/L H_2SO_4 electrolyte. Cycling test of the same sample also shows excellent long-term cyclic stability, which has lost less than 2% of the total specific capacitance after 2000 cycles. These results indicate that the prepared $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ materials are excellent candidates as electrode materials for supercapacitors.

Key words: $\text{SnO}_2 \cdot x\text{H}_2\text{O}$; hydrolysis precipitation process; supercapacitors; electrochemical performance

Supercapacitors have received great attention in the field of electrochemical energy storage and conversion due to their ability of delivering high levels of electrical power and long cycle life^[1]. They can be categorized as electric double-layer capacitors (EDLCs) and faradaic pseudo-capacitors. EDLCs use the physical separation of electronic charge in the electrode and ions of the electrolyte adsorbed on the surface of electrode. And an optimal faradaic pseudocapacitors are charged by chemical sorption of a working cation of the electrolyte at a reduced complex at the surface of the electrode^[2]. Many oxides, such as RuO_2 ^[3], MnO_2 ^[4], NiO ^[5] and Co_3O_4 ^[6] have been widely reported in the applications of faradaic pseudo-capacitors due to high specific capacitance.

Tin oxide (SnO_2) is now widely used in catalysis, gas sensors and lithium batteries^[7-9]. Recent research towards the application of SnO_2 as supercapacitor materials has also brought much attention to the society. Selvan et al. synthesized SnO_2 and SnO_2/C by reactions under autogenic pressure at elevated

temperatures, and SnO_2/C has a specific capacitance of 37.8 F/g^[10]. In the meantime, Wu reported that $\text{Fe}_3\text{O}_4/\text{SnO}_2$ composites delivered specific capacitance of 33 F/g in Na_2SO_4 electrolyte^[11]. Besides, thin films of $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ have been synthesized via a simple successive ionic layer adsorption and reaction method, delivering specific capacitance of 25 F/g in Na_2SO_4 electrolyte^[12]. Similarly SnO_2 thin films were deposited by chemical route, showing specific capacitance of 66 F/g in Na_2SO_4 electrolyte^[13]. While tin oxide thin films were prepared via a spray pyrolysis method, showing specific capacitance of 168 F/g in KOH electrolyte^[14]. When amorphous tin oxide was potentiodynamically deposited onto stainless steel electrode, a specific capacitance of 285 F/g could be obtained^[15]. We deduce that SnO_2 prepared at lower temperature delivers higher specific capacitance. And by comparing other oxides, such as RuO_2 , the SnO_2 usually has higher specific capacitance in the form of hydrate.

In the report of Lee et al., strong acid H_2SO_4 electrolyte was

found to be better than mild KCl^[2], and SnO₂ was confirmed to be stable in H₂SO₄ electrolyte^[16]. In order to improve the electrical conductivity, tin oxide hydrate need to be annealed, but the specific capacitance tends to be low if the temperature is much higher^[17]. In the present work, SnO₂·xH₂O electrode materials have been synthesized by hydrolysis precipitation process and the effect of calcination temperature on the structure and the electrochemical performance of SnO₂·xH₂O has been investigated.

1 Experiment

SnO₂·xH₂O materials were synthesized by adding 144 mL of 2.5 mol/L ammonia solution to 60 mL of 1 mol/L SnCl₄ solution in an ice bath from 0 °C to 4 °C and stirred at around 3000 r/min thoroughly for 4 h. Then the resulting precipitate was collected by centrifugation, and washed several times with ethanol, then dried at 80 °C for 2 h. The precipitate was separated and calcined at 100, 150, 200, 250 and 300 °C for 2 h. The samples obtained were designated as SH-100, SH-150, SH-200, SH-250 and SH-300 accordingly.

XRD analysis was conducted using Deutschland RUKERD2 PHASER X-Ray diffractometer. TEM analysis was carried out with JEOL 2010 microscope. TGA analysis was carried out in N₂ using STAPT-1000 Deutschland LINSEIS thermogravimetric analyzer. The electrode was formed by mixing 75 wt% SnO₂·xH₂O, 20 wt% super P, and 5 wt% PTFE as binder. Each of the slurry was then rolled into a thin sheet of titanium mesh. The electrochemical performances of the electrodes were studied in a three-electrode system in 0.5 mol/L H₂SO₄ electrolyte with CHI660C electrochemical workstation, where the SnO₂·xH₂O electrodes, platinum plate and saturated calomel electrode were applied as the working electrode, counter electrode and reference electrode, respectively. The electrochemical performances of SnO₂·xH₂O were tested using a CV method, chronopotentiometry and cycling test. The specific capacitance of the electrode can be calculated from the CV curves according to the following equation:

$$C = \frac{Q}{\Delta E \cdot m} \quad (1)$$

where C (F/g) is the specific capacitance, Q (C) is the average charge, m (g) is the mass of the SnO₂·xH₂O in the electrode, and ΔE (V) represents voltage range.

The capacitance from the constant current charge-discharge curve can be calculated using the following equation:

$$C = \frac{It}{\Delta E \cdot m} \quad (2)$$

where I (A) represents the total current, t (s) is the discharge time, the ΔE (V) represents potential during constant current discharge.

2 Results and Discussion

2.1 Structural study, thermal analysis and surface morphology

Fig.1a shows XRD patterns of SnO₂·xH₂O at around 26.6°, 33.9°, 51.8°, 64.7°, indexed as (110), (101), (211) and (112) planes, respectively with tetragonal rutile structure SnO₂, which is corresponding to JCPDS files No.41-1445. It is observed that the peaks are relatively broadened, which further indicates that the materials have low crystallinity. It is noted that the diffraction intensity increases and the full-width at half-maximum (FWHM) of diffraction peaks reduces with the increase of the annealing temperature, revealing the enhancement of the crystallization of the materials.

TGA curves was used to determine the water content of SnO₂·xH₂O. It is found in Fig.1b that the SnO₂·xH₂O can stabilize to a temperature as high as 500 °C. There are two mass loss steps in the temperature range^[18]: The first step ends at 175 °C of SH-100, SH-150, SH-200, SH-250 and SH-300 with loss of mass 11%, 10%, 8%, 8%, and 6%, respectively. This effect is reasonably attributed to the absence of physically adsorbed water^[19]. Then the water content of the SnO₂·xH₂O materials is 12wt%, 7wt%, 7wt%, 5wt%, 6wt%, respectively. Theoretical mass loss of SnO₂·xH₂O approaches to anhydrous SnO₂. The above results indicate that percentage content of water in the SnO₂·xH₂O decreases as the calcination temperature increases.

The effect of annealing temperature on the morphology of SnO₂·xH₂O can be directly observed from the TEM images in Fig.2. SnO₂·xH₂O mainly consists of randomly dispersed, spherical particles. The TEM images reveal that the particles are mainly dispersed with submicron size and their outer surfaces are constructed of many small nanoclusters that are rapidly grown from the center of the spheres. The crystallinity of the SnO₂·xH₂O also increases with the increase of the temperature.

2.2 Electrochemical performance

Fig.3 shows the CV responses of SnO₂·xH₂O at the scan rate of 5 mV/s. All curves show rectangular shapes within the measured potential window, indicating a better ideal electrical and good capacitive behavior.

Fig.4 displays cyclic voltammograms of SH-200 in 0.5 mol/L H₂SO₄ electrolyte at different scan rates. It also can be observed that the response current of the electrode almost reverses instantaneously when the scan direction changes whether from anodic to cathodic scan or from cathodic to

Fig.2 TEM images of $\text{SnO}_2 \cdot x\text{H}_2\text{O}$: (a) SH-100, (b) SH-150, (c) SH-200, (d) SH-250, and (e) SH-300

Fig.3 CV curves of $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ in 0.5 mol/L H_2SO_4 electrolyte at the scan rate of 5 mV/s

Fig.4 CV curves of SH-200 in 0.5 mol/L H_2SO_4 electrolyte at different scan rates

anodic scan. And the integral area of CV curves increases with increasing of the scan rate, which indicates that the voltammetric currents are directly proportional to the scan rate^[20].

The variation in the specific capacitance calculated from

CV curves of the $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ as a function of the scan rate is plotted in Fig.5. At the scan rate of 5 mV/s, the specific capacitances of SH-100, SH-150, SH-200, SH-250, and SH-300 reach 18.1, 18.5, 36.1, 26.5 and 23.9 F/g, respectively. The specific capacitance of SH-200 is higher than the reported values of SnO_2 synthesized by wet chemical techniques (5.3 F/g at 25 mV/s in a 0.1 mol/L H_2SO_4 electrolyte)^[21]. And the specific capacitance of 19.6 F/g is obtained even at a higher scan rate of 200 mV/s for SH-200, and SH-200 has a higher capacitance value compared with other samples at any scan rate. This comparative decrease in the specific capacitance at higher scan rates is mainly attributed to the increase in ionic resistivity and the ion inaccessibility of the electrode surface at high charging-discharging rates^[22]. The SH-200 is better because more anhydrous SnO_2 will form when water is irreversibly lost from structure upon annealing in air, resulting in an increase in the metallic conduction paths but a decrease in the volume of protonic transport paths^[23].

The charge-discharge behavior of SH-200 was measured by chronopotentiometry from 0 V to 0.9 V at a constant current of 0.005 A and the result is shown in Fig.6a. The specific capacitance of the $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ derived from the discharge curve is found to be 32.0 F/g at 0.005 A, which is close to the value of 36.1 F/g derived from the cyclic voltammogram at the scan rate of 5 mV/s.

The cycle stability was also investigated over 2000 cycles for SH-200 electrode at a scan rate of 20 mV/s. Fig.6b shows the specific capacitance retention as a function of cycle

Fig.5 Dependence of specific capacitance of $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ as a function of scan rates

Fig.6 Chronopotentiometry curve of SH-200 at 5 mA in 0.5 mol/L H_2SO_4 electrolyte (a) and capacity retention of SH-200 in the scan rate of 20 mV/s as a function of cycle number (b)

number. A decrease of 2% of the specific capacitance is observed after 2000 cycles. This long-term electrochemical stability indicates that this kind of material have a long-term electrochemical stability.

3 Conclusions

1) Hydrolysis precipitation process is a simple and efficient way to fabricate $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ electrode materials.

2) $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ crystallite with a tetragonal rutile structure is formed directly and the crystallinity increases with the increase of temperature. The synthesized materials are determined to be hydrate. The crystallinity and particle size of the $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ increase with the increase of temperature.

3) The synthesized materials possess typical capacitance behavior within a potential range from 0 to 0.9 V in 0.5 mol/L H_2SO_4 electrolyte. The $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ materials calcined at 200 °C is a suitable candidate for super-capacitors application as it has a specific capacitance of 36.1 F/g. This kind of materials has a long-term electrochemical stability.

(上海工程技术大学, 上海 201620)

摘 要: 采用水解沉淀法制备 $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ 电极材料。经过不同温度的焙烧, 将得到的 $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ 电极材料用 X 射线粉末衍射 (XRD), 透射电子显微镜 (TEM) 和热失重测试 (TGA) 进行分析。XRD 测试表明, $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ 电极材料为金红石结构。TEM 证实了 $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ 的形貌。TGA 表明, 随着焙烧温度的升高, $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ 含水量降低。通过循环伏安法, 恒流充放电和循环寿命研究了 $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ 的电化学行为。CV 测试表明, 在 200 °C 下焙烧的 $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ 电极材料在 5 mV/s, 0.5 mol/L H_2SO_4 中的比电容为 36.1 F/g。经过 2000 次循环后, 比电容与首次循环的比电容相比减少了 2%。这些结果表明用化学沉淀法制备的 $\text{SnO}_2 \cdot x\text{H}_2\text{O}$ 是超级电容器良好的候选材料。
